Recent Changes in Earnings Distributions in the U.S.: Age and Cohort Effects

Kelvin R. Utendorf, Social Security Administration

Earnings have traditionally served as one measure of a person's well-being. Other things being equal, an increase in an individual's earnings is generally thought to signify an improvement in that individual's lot. Likewise, at a group or national level, increases in average earnings are often viewed as an indication that the group or nation is, in some sense, better off than before the increase. Increasing earnings disparity among groups is commonly viewed as being bad, however. An increase in the earnings of one group relative to those of another group could mean that society as a whole is worse off, depending on one's point of view. Examining changes in earnings distributions provides us with insights into the welfare of individuals and groups in society. In addition, the ability to forecast earnings plays a central role in accurately projecting the future status of Social Security's OASDI (Old-Age, Survivors, and Disability Insurance) Trust Funds. One part of developing an earnings forecast involves understanding how past earnings distributions have changed over time, with the hope that this understanding will provide insights as to what to expect in the future.

In this paper, I describe changes in earnings distributions over the period 1981-1995, for the overall population, as well as by age and birth cohort subgroups, using data extracted from the Social Security Administration's earnings records. Since these data have not been extensively used for this type of research in recent years, the second section of the paper describes them thoroughly. These data offer several advantages over the typical public-use survey dataset, as indicated in the next part of the paper. The third section contains a description of the methods used to examine changes in the patterns of earnings distributions over the period. Gini indices have long been used to examine earnings inequality issues. Two relatively recent innovations regarding the Gini index, used heavily in this paper, are introduced in this third section. Results are presented in the fourth section. The fifth section concludes the paper.

■ Data Description

I use a subset of files from the Social Security Administration's Continuous Work History Sample (CWHS) family of files for this project. In particular, I use the 1-percent sample 1957-1990 Longitudinal Employee-Employer Data (LEED) file and the 1991, 1992, 1993, 1994, and 1995 files from the 1-percent sample annual Employee-Employer (EE-ER) file series in order to examine earnings distributions over the period 1981-1995. When used in combination with the CWHS 1-percent sample Active file,[1] I have information on the year of birth, annual Social Security taxable wages, and total wage compensation for a 1-percent sample of Social Security numbers (SSN's) for which wage and salary employment was reported over the period 1981-1995.[2, 3]

I chose to explore the interval 1981-1995 for two reasons. Increasing earnings inequality over the 1970s and the early to mid-1980's has been well documented in numerous studies,[4] while there is much less work covering the late-1980's and early-1990's. By examining distributions over 1981-1995, I am able to corroborate the results of other studies for the period of the early to mid-1980's, while using a consistent method to study possible changes in the earnings distributions from more recent years.

A second reason for choosing the period 1981-1995 arises because of limitations in the Social Security Administration's administrative data themselves. In 1978, a change from quarterly wage reporting to annual wage reporting took place. As part of this change, total wage and salary compensation (taken directly from the W-2 information reported by employers to SSA) became available within the CWHS family of files.[5] However, as with any major modification, there were difficulties in the years immediately following the change to annual wage reporting with late posting, duplicate reports, and other processing problems. In order to avoid pos-

sible problems with this transition period, I elected to use 1981 as the earliest year in the study.[6]

Using data from the CWHS family of files provides several advantages over the data typically used for this type of research. First and foremost, because they come directly from the W-2 form, the CWHS earnings data do not exhibit any of the "self-reporting" problems which have the potential for being present in most, if not all, public-use surveys. In particular, it is believed that individuals toward the upper end of the earnings distribution have a higher tendency to incorrectly report their earnings in surveys, which is troublesome when the point is to examine earnings distributions. Data from the CWHS do not have this problem since individuals generally do not have a choice regarding what is reported on their W-2 forms.[7]

A second advantage of using data from the CWHS family of files is that the earnings data are not top-coded. Public-use datasets top-code earnings in an effort to help mask the identity of individuals with high earnings who might otherwise be identifiable with a combination of their actual earnings and other characteristics in the file. The Annual Demographic Survey (March CPS Supplement) of the Current Population Survey (CPS), for example, presently top-codes wage and salary earnings so that an individual does not show earnings in any one job of more than $100,000 per year.[8] The percentage of individuals in a survey affected by this can vary from year to year, which means top-coding alone, other things being equal, could cause measures of earnings inequality to vary from year to year. Given that one of my objectives is to make accurate observations regarding the fluctuations in earnings distributions from year to year, using data that are not top-coded is important.

A third advantage of the CWHS is the large number of observations available. For the LEED and EE-ER files, a 1-percent sample, based on specified digits from the last four digits of the SSN, of those with wage and salary earnings in the specified year(s) is drawn from Social Security's records. Sample sizes for the years studied range from about 970,000 to about 1.36 million observations, depending on the year in question.[9] Such large sample sizes eliminate concerns about having too few individuals in any particular group under study.

There are certain disadvantages to using these particular data when analyzing changes in earnings distributions. Probably the biggest drawback is the lack of certain types of socioeconomic information for the individuals in the dataset, particularly the lack of information regarding educational attainment. Many studies have pointed to differential educational attainment levels as a possible reason behind increases in earnings inequality over the 1970's and the 1980's. Without any way to identify the schooling level reached by the individuals in the sample, the ability to explain changes in earnings distributions using these data is limited.[10]

A second disadvantage to using these data is the work required to make them suitable for research purposes. The primary reason that the Social Security Administration collects this information is to assist in effectively administering the program so that the monthly benefit payments to recipients are delivered on a timely basis and in the correct amounts. Researchers within SSA, in effect, have access to these data as an afterthought and necessarily spend a great deal of time making them useful for research purposes.

Each observation in the sample, in addition to the limited demographic information, contains two earnings variables, Social Security taxable earnings and total wage and salary earnings.[11] Social Security taxable earnings are earnings, up to the annual maximum taxable earnings amount,[12] by individuals covered by the Social Security program. The total wage and salary earnings information comes directly from an individual's W-2 form, as indicated earlier, *regardless of whether or not that individual is covered by the Social Security program.* There are observations for which the amount in the total wage and salary earnings field in the dataset is less than the amount in the Social Security taxable earnings field. This could occur if the individual in question contributed to a tax-deferred saving plan, since the earnings amount reported in the total wage and salary field in the dataset does not account for contributions to such plans.[13] It is also possible for the amount in the total wage and salary earnings field to be less than the amount given in the Social Security taxable earnings field due to the way that Social Security processes these data. For example, if a correction is made to the taxable earnings amount, it is generally the case that the corresponding total wage

and salary earnings amount is not updated to reflect the change, since, from a programmatic standpoint, the total wage and salary earnings amount is not important in the determination of benefits. Therefore, for observations (over the years 1981-93) where the total wage and salary earnings amount was less than the taxable earnings amount, the former was increased to the level of the latter in order to give a better accounting of the individuals' true total earnings, reflecting both the view that true total earnings should include the deferred earnings, as well as the belief that the taxable earnings amounts on record are the more accurate of the two.[14, 15]

For the years 1994 and 1995, additional earnings information is available in the EE-ER files. In particular, Medicare (HI) taxable earnings are available for each observation, which is important since, beginning in 1994, the ceiling on maximum HI taxable earnings was eliminated, meaning that the Medicare taxable earnings variable provides (potentially) an excellent measure of total wage and salary earnings since even deferred earnings are taxed for Medicare purposes. A measure of deferred compensation is also included with the information for the years 1994 and 1995.

This additional information provides somewhat of a dilemma, however. While filtering the files so that the largest of either the wage and salary earnings variable plus the deferred compensation variable, the OASDI taxable earnings variable, or the HI taxable earnings variable is used as my analysis variable will be likely to give a more accurate measure of total wage and salary earnings, doing so will decrease slightly my ability to make comparisons across years since the series will no longer be consistent. Accordingly, I have performed all of the analyses using both the "new" method (looking for the largest value among HI taxable earnings, OASDI taxable earnings, and wage and salary earnings plus deferred compensation) and the "old" method (using only the variables available to me for the years 1981-1993) for the years 1994 and 1995. As the results show, using the additional information in the 1994 and 1995 files does have an impact.[16]

I applied one other significant filter to the data by eliminating all observations for individuals younger than age 14 or older than age 85.[17] These rather arbitrary age cutoffs were chosen to eliminate from the sample those observations for which either very young individuals or very old individuals had large wage and salary earnings.[18] While it is conceivable that the very young or the very old might have significant levels of income, it is much less likely that individuals in either of those groups would have large wage and salary earnings.

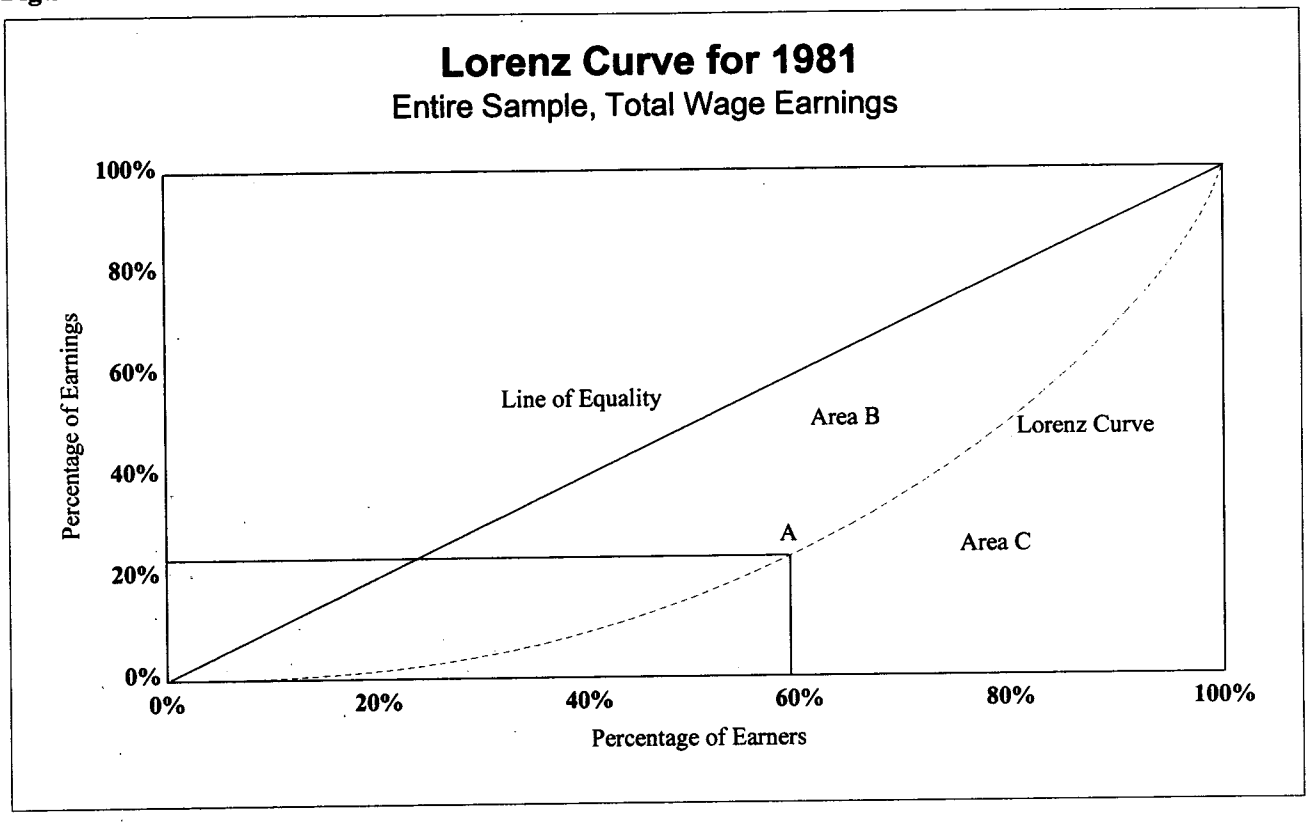
■ Measuring Earnings Inequality

Many different measures of earnings inequality have been developed over the years.[19] Perhaps the most commonly used measure, and the measure I employ in this paper, is the Gini coefficient. The traditional Gini coefficient is defined as being half of the absolute mean difference in earnings between each pair of individuals in the sample, relative to mean earnings for the sample.[20] In other words, it is a measure of the spread between the earnings of all pairs of individuals in the sample.

The Gini coefficient can be represented graphically with the use of a Lorenz curve, as in Figure 1. The Lorenz curve in the example is a plot of the cumulative percentage of total earnings versus the cumulative percentage of earners, where the observations are ranked from lowest earnings to highest earnings. Point A on the Lorenz curve in Figure 1, for example, shows that the bottom 60 percent of the earners in the sample (bottom with respect to their position in the earnings distribution) earned approximately 25% of the total wage and salary earnings in the U.S. in 1981. The "Line of Equality" shows where the Lorenz curve would be positioned if everyone in the sample had equal earnings. Therefore, the greater the distance between the Lorenz curve and the Line of Equality, the greater the inequality present in the sample. The traditional Gini coefficient is equal to the ratio of the area between the Line of Equality and the Lorenz curve and the area beneath the Line of Equality, in other words, Area B divided by Areas B+C. As Area B gets smaller (meaning the Lorenz curve gets nearer to the Line of Equality and inequality decreases), the Gini coefficient gets smaller.

Two recent innovations regarding the Gini coefficient enhanced its usefulness for this project: work by Barrett and Pendakur (1995) regarding the asymptotic distribution of generalized Gini indices and work by

Figure 1



Yitzhaki and Lerman (1991) on Gini decomposition. What follows is a brief overview of each of these new developments, as well as an explanation of their importance.

S-Gini Indices

The traditional Gini index, though widely used, has been criticized because it does not allow inequality to be measured under different value judgements regarding the importance of one part of the earnings distribution relative to another. Partly in response to this criticism, Donaldson and Weymark (1980) and Yitzhaki (1983) independently developed what is known as the S-Gini class of inequality indices, and in particular, the S-Gini relative indices of inequality that I use in this paper. The S-Gini indices depend on a parameter, $\delta \geq 1$, that can be adjusted to reflect the sensitivity of the index to different parts of the earnings distribution.[21] For values of δ greater than 2, for example, the index places more weight on the earnings of those at the lower end of the earnings distribution. When $\delta = 2$, the index places equal weight on all of the observations and corresponds to the traditional Gini coefficient.

The real value of the S-Gini indices for this paper, though, is that they are calculated by using Lorenz curve ordinates[22] and, therefore, use information from every part of the range of earnings. Beach and Davidson (1983), Bishop, Chakraborti, and Thistle (1989), and Bishop, Formby, and Smith (1991) developed statistical inference techniques to study income and earnings inequality by examining Lorenz curve dominance among different distributions. Barrett and Pendakur extend the previous work on S-Gini indices by deriving their large sample properties, using methods similar to those used by Bishop *et al.* for Lorenz curves, thereby making it possible for S-Ginis to be used for statistical inference.[23] With the traditional Gini coefficient, one is unable to assess whether there is a statistically significant differ-

ence between a Gini of .530 and one of .540, for example. By deriving the large sample properties of the S-Gini indices, however, Barrett and Pendakur make it possible to determine whether there is a statistically significant difference between S-Gini estimates. This is important in this paper because it allows inferences regarding the likelihood that the distribution of earnings, as measured by the S-Gini coefficient, has changed over time.

Gini Decomposition

Typically, the Theil entropy inequality measure has been used in studies such as this because it decomposes nicely into two terms that can be thought of as measures of between- and within-group inequality. However, recent work by Yitzhaki and Lerman (1991) on decomposing the Gini coefficient has breathed new life into the measure and allowed me to use a consistent measure of inequality across all parts of this paper.

Yitzhaki and Lerman showed that the Gini index of inequality can be decomposed into three terms, one term representing between-group inequality, a second term representing the weighted sum of within-group inequality indices, and a third term representing the weighted sum of group stratification indices.[24, 25] Stratification is a concept borrowed from sociology and refers to the division of a society into hierarchically arranged groupings where the members of a group have similar qualities. Yitzhaki and Lerman develop what they refer to as "indices of stratification," which capture the degree of overlap between group members and non-group members with respect to some quality, namely earnings. I use what they have defined as a relative index of stratification to examine the extent to which the earnings of certain age and cohort groups overlap with the earnings of other age and cohort groups.

The relative stratification index of Yitzhaki and Lerman, Q_i, ranges from -1 to 1.[26] If it is the case that Q_i=1, then no members of groups other than i have earnings within the range of earnings spanned by the members in group i, meaning group i forms a perfect stratum. As Q_i decreases from 1, group i forms less and less a stratum in the overall population as the earnings of more and more non-group i members fall within the range spanned by group i earnings. At Q_i=0, group i does not form a stratum at all since the relative rank of each person within his or her own group is identical to his or her rank in the overall population. Negative values for Q_i mean that "group" i really is not a single group, but is instead composed of several different groups. Finally, were Q_i=-1 to be true, "group" i would actually consist of two distinct groups, with those groups located at opposite ends of the earnings distribution. In this case, the earnings of everyone in the sample *other* than those in group i would lie between the ranges of the two segments of group i earnings, meaning that group i would form two perfect, distinct strata.

Results

Table 1(a) shows the real sample means, real medians, and the S-Gini coefficients for total wage and salary earnings for the entire sample.[27, 28] The S-Gini coefficients (the last column in the table) and the asymptotic standard errors were calculated on the basis of 100 sample quantiles. The decision to use 100 quantiles for calculating the S-Ginis was somewhat arbitrary, though the S-Ginis presented in Table 1 for the case of δ =2 (the "traditional" Gini coefficient where all observations are equally weighted) are identical to those calculated via the covariance method of Lerman and Yitzhaki (1984) to at least three decimal places.[29, 30]

Table 1(a) shows that both the mean and median earnings of those in the sample grew slowly over the period of this study, with mean earnings increasing by only 15 percent and median earnings increasing by an even smaller 4 percent over the 15-year period. Table 1(b), using a consistent method of calculating total wage and salary earnings over all of the years, shows even slower growth in real mean and median earnings. Both tables show median earnings peaking in 1987 and generally declining thereafter. The stagnant earnings growth might be partly attributed to an increase in part-time/part-year employment over the period of the study, since the sample contains individuals with both types of employment.

The last column in both parts of Table 1[31] contains S-Gini coefficients (with asymptotic standard errors beneath the coefficients) for each year of the study. Clearly,

by this measure, earnings inequality generally increased (by statistically significant amounts) over the period of the study. In an earlier paper covering the period 1981-1993,[32] I observed that earnings inequality had generally decreased from 1988 on and speculated that perhaps this signaled a turnaround in the trend of increasing earnings inequality. After updating those data and adding two additional years of observations, it is clear that, while earnings inequality decreased slightly over the period 1988-1991, the overall trend is still upwards. In fact, the S-Gini coefficients for the years 1992-1995 are statistically significantly greater (higher inequality) than those in any other year in the study.

Comparing the statistics for years 1994 and 1995 in Table 1(a) with those in Table 1(b) clearly shows the effect of being able to use HI taxable earnings in determining total wage and salary earnings. Mean earnings for 1994 and 1995 are higher in Table 1(a) than in 1(b), reflecting the fact that there are many cases in which HI taxable earnings for an observation are greater than the combination of wage and salary earnings and deferred compensation. The S-Gini coefficients, being higher in Table 1(a) than in 1(b), also reflect the fact that higher than average earnings are picked up when the HI taxable earnings variable is utilized. As it is generally believed that the OASDI and HI taxable earnings variables are of higher quality than the total wage and salary earnings and deferred compensation variables in SSA's administrative records, it is likely that the statistics for 1994 and 1995 presented in Table 1(a) more accurately reflect reality for those two years.

Table 2 shows earnings share by decile for the entire sample over 1981-1995. The most striking thing about Table 2 is the large increase in the share of earnings garnered by the decile at the top of the earnings distribution. This increase, from 30.78 percent in 1981 to 35.83 percent in 1995 (from Table 2(b)), comes at the expense of all other parts of the earnings distribution. The earnings shares also generally reaffirm the patterns found in the S-Gini coefficients in Table 1. The earnings share increased for the upper decile over 1981-1988, while the shares generally fell for the other deciles, corresponding to the increasing S-Gini coefficients over that period found in Table 1. From 1988 to 1992, the earnings share for those in the upper decile remained relatively steady, while shares for those in the lowest five deciles mostly increased, explaining the decreasing S-Gini coefficients over that period. From 1992 to 1994, earnings shares for the lower eight deciles showed generally large (in percentage terms) decreases, while shares for the upper two deciles showed increasingly large gains as one moves upwards along the earnings distribution, a fact again reflected in the large increase in the S-Gini coefficient from 1992 to 1994 in Table 1. Finally, note that the numbers in Table 2(a) indicate that the share of earnings received by the upper decile is even larger, if one believes in the higher accuracy of the HI taxable earnings variable in SSA's administrative earnings files, than indicated in Table 2(b). The disparity in earnings between those in the upper decile and those in the lower decile is quite large, just as one would expect given the S-Gini coefficients.

Table 3 presents various earnings distribution statistics by age group. I rather arbitrarily chose to set the age ranges for the groups at 14 to 24, 25 to 34, 35 to 54, 55 to 64, and 65 to 85.[33] The first age group encompasses individuals who are still in school or who are relatively early in their careers. Those in the second age group are likely out of school and working, but members of this group are more likely to change jobs several times while searching for the "right" job. The third group consists of individuals in the core of their working lives, people who are likely to have fewer dropout years than those in the younger two age groups. Group four, the 55 to 64 year olds, are probably nearing the end of their working careers and preparing to retire. Finally, age group five is composed of those over 65 who are likely retired or working only part time.

The "Mean earnings" numbers in Table 3 show that those in both the 14 to 24 and 25 to 34 age groups had lower real mean earnings in 1995 than they did in 1981, while those in the other age groups all enjoyed increases in mean earnings over the period. Partly, this might be a function of individuals staying in school longer, or of relatively more individuals pursuing a college education in 1995 than in 1981, particularly for the youngest age group. The patterns of earnings increases and decreases for each of the groups are also interesting. Earnings for the youngest age group generally declined over time. For all of the other age groups, mean earnings

generally increased until 1987 or 1988, then mostly declined slightly from that point.

Also interesting are the patterns present in the "Proportion of sample" figures in Table 3. The aging of the "baby boom" generation stands out clearly, as demonstrated by the fact that the number of 14-to-24-year-olds in the sample decreased dramatically, while at the same time, the relative number of 35 to 54 year olds increased substantially.[34] The only other age group to increase in relative size over the period 1981-1995 is the 65 to 85 year olds, with all of the increase occurring since 1988. In part, this might be a sign that individuals are working longer, perhaps part time, or that they are re-entering the labor force after retirement. More work is needed to investigate this phenomenon.

As could be predicted from the mean earnings and proportion of sample numbers, the share of earnings garnered by the youngest two age groups fell sharply from 1981 to 1995. Also, as expected, those in the 35 to 54 age group enjoyed a large increase in their share of earnings, with an increase from about 43 percent of the earnings in 1981 to nearly 58 percent of the earnings in 1995. Those in the top age group also enjoyed an increase of nearly 15 percent in their share of earnings over the period.

As found by Utendorf (1998) and others, the largest contributor to overall earnings inequality is within-group inequality. The "Within-group Ginis" and "Within-group inequality term" numbers in Table 3 bear this out. The youngest and the oldest groups had the most unequal distribution of earnings within their groups, with the Gini coefficients for both groups being greater than the overall Gini coefficient for every year in the sample. Especially for those in the 65 to 85 years old group, there is a great deal of earnings disparity, with the Gini coefficients reaching as high as 0.702 in 1994. Interestingly, those in the 25 to 34 age group had the lowest within-group inequality for every year in the sample. It is unclear why earnings inequality within that group would be substantially lower than within any other group.

The "Stratification index" figures in Table 3 show that the youngest three age groups became increasingly stratified over the period 1981-1995 in the sense that they increasingly occupied distinct segments of the earnings distributions during those years. For example, in 1995, over 89 percent of the 14 to 24 year olds in the sample had earnings below the median earnings of the entire sample, with this higher concentration of 14 to 24 year old earners at the lower end of the earnings distribution leading to the high relative stratification number. The fact that the stratification index for the oldest age group became increasingly negative implies that that "group" increasingly became more than one group. It is likely that there were relative increases in the numbers of those in the oldest age group who continued to work full time and enjoy relatively higher earnings, separating themselves, at least along the earnings dimension, from the low earners in their age group.

The between-group inequality term in Table 3 generally increases over the period from 0.089 in 1981 to 0.104 in 1995, meaning that, by this measure, the age groups identified in the paper became less equal with regard to earnings over the period.[35] This result is to be expected, given the decrease in the relative share of earnings by all but the 35 to 54 and the 65 to 85 age groups. In addition, the increasing stratification of the three youngest age groups would imply that the earnings of those three groups are growing less equal.

Comparing the 1994 and 1995 columns of Tables 3(a) and 3(b) once again shows the consequences of considering HI taxable earnings (Table 3(a)) when formulating the total wage and salary earnings variable. The mean earnings for the various age groups are higher in Table 3(a), as is to be expected. Also, given that using the HI taxable earnings information likely leads to increases in the reported earnings of high earners more often than in the reported earnings of low earners, it is hardly surprising that the overall and within-group Gini coefficients are higher in Table 3(a). It is somewhat surprising that the stratification index for 14 to 24 year olds is lower in Table 3(a) than in Table 3(b), meaning that using HI taxable earnings decreases the distinctiveness of the youngest age group along the earnings dimension. The reason(s) behind this are unclear and merit further work.

Table 4 shows the decomposition of the overall annual Ginis by birth cohort for total wage and salary earn-

ings. As with choosing the age categories to use, I made somewhat arbitrary choices with regard to the years spanned by each birth cohort. I elected to use birth cohorts that covered 10-year periods in order to simplify the analysis and in the belief that the birth cohorts chosen provide insights into the overall effects the cohort one is born into have on one's place in the earnings distribution. In addition, the birth cohorts were chosen with the idea of keeping the individuals in the sample between the ages of 14 and 85 during the beginning and ending years of the study period.[36]

The "Mean earnings" numbers in Table 4 show the expected pattern. Those in the 1909 to 1918 and the 1919 to 1928 birth cohorts have generally declining real mean earnings over the period as those who remain in the labor force move to part-time/part-year employment. Those in the most recent three birth cohorts, 1939 to 1948, 1949 to 1958, and 1959 to 1968, show generally increasing mean earnings over time as they either move into their prime earnings years (those in the 1939 to 1948 and the early 1949 to 1958 birth cohorts) or they move from part-time jobs while in school to full-time, post-education jobs (the most recent birth cohort). Interestingly, only the 1929 to 1938 birth cohort experiences increasing, then decreasing mean earnings over the period of the study. Evidently, enough of the older members of the birth cohort move into part-time/part-year employment after "retirement" to cause mean earnings for the group to begin declining after 1988.

The figures in the "Proportion of sample" section of Table 4 show the effects of attrition, either due to death or to exiting the labor force, by those in the oldest birth cohorts. The proportion of those in the sample from the oldest three birth cohorts decline steadily over time, while the proportion of those in the two most recent birth cohorts increases over the period in question. On the surface, it appears odd that the proportion of those born between 1939 and 1948 initially declines, but then increases over the years of the study since those individuals should be in or near their prime working ages throughout the years studied. However, when one examines the actual numbers, one does see small declines in the numbers of individuals in that birth cohort towards the terminal years of the study. The sample size is shrinking more quickly, however, because of the attrition from the three oldest birth cohorts, thus leading to the slight increases in the proportion of the sample attributed to those born between 1938 and 1948.

Given the Mean earnings and the Proportion of sample numbers, the figures in the "Earnings share" category of Table 4 are to be expected, at least for those in the oldest three and the two most recent birth cohorts. The earnings share garnered by those in the oldest three birth cohorts declined rather steadily, for the most part, over the years 1981-1995. Those in the two most recent birth cohorts enjoyed relatively large increases in earnings share, particularly those in the 1959 to 1968 birth cohort. The share of earnings for those in the 1939 to 1948 birth cohort actually declined slightly over the 15 years of the study despite the fact that the group's mean earnings increased and that they formed a slightly larger part of the sample in 1995 than they did in 1981. The explosive growth of the mean earnings of those in the 1959 to 1968 birth cohort, as well as their relative increase in size, account for most of the decline in the earnings share experienced by the 1939 to 1948 birth cohort.

Several interesting patterns emerge from the "Within-group Ginis" numbers in Table 4. For every birth cohort but the most recent one, the within-group Gini coefficients increase, for the most part, throughout the 1981-1995 period. For the 1959-1968 cohort, though, the within-group Gini coefficients decrease substantially from 1981 to 1991 before reversing course and increasingly slightly from 1992 through 1995. This seems to indicate that the increasing mean earnings of the group come about because those who were low earners in 1981 "caught up" somewhat, over the years of the study, with those who were higher earners in 1981. Another pattern present in the numbers is that the smaller birth cohorts (smaller in the sense of being a smaller proportion of the sample) generally have the higher Gini coefficients. It is likely that a relatively small number of individuals had high earnings for the 1909-1918 birth cohort in 1994, while the rest of the group had relatively low earnings, thus leading to the high 0.744 Gini coefficient. Finally, it is interesting to note that the 1959-1968 birth cohort had the second highest Gini coefficient each year through 1984. From that point on, the decline in Gini coefficient of that birth cohort, combined

with the increases in the Gini coefficients of the other birth cohorts, results in the 1959-1968 birth cohort having the lowest within-group Gini coefficient by 1995.

The "Stratification index" numbers in Table 4 are a mixed bag. The increasingly negative index numbers of the oldest birth cohort indicate that the "group" became less and less one group over the period, at least along the earnings dimension. This corroborates the story told by the within-group Gini coefficients for the 1909-1918 group of there being a group of relatively high earners and a group of relatively low earners in that birth cohort, especially during the latter years of this study. The 1919-1928 birth cohort went from being a slightly stratified group to being more than one distinct group from 1981-1995, while the 1929-1938 birth cohort moved from being slightly stratified in 1981 to being non-stratified in 1995. The most recent birth cohort was moderately stratified in 1981, but, like the 1929-38 birth cohort, occupied less and less of a distinct stratum as time went by. The 1939-48 cohort, on the other hand, became increasingly stratified over the period, moving from being the second least stratified group in 1981 to the most stratified group in 1995.

Within-group inequality is again the most important contributor to overall earnings inequality for the birth cohorts chosen, as shown by the "Within-group inequality term" numbers in Table 4. While between-group inequality exists (as shown by the "Between-group inequality term" numbers), it clearly does not influence overall earnings inequality as much as within-group inequality. It is interesting to note, however, that within-group inequality is relatively constant over the period 1987 to 1995, and that much of the growth in overall earnings inequality comes from growth in between-group inequality, at least by this measure of earnings inequality.

The differences between Tables 4(a) and 4(b) are similar to the differences between the "a" and "b" tables discussed earlier in various parts of this paper. Using HI taxable earnings in determining total wage and salary earnings in Table 4(a) results in higher mean earnings for every age group in 1994 and 1995. These differences are not distributed evenly across the earnings distribution within age groups, however, resulting in higher within-group Gini coefficients across the board for 1994 and 1995 in 4(a) than in 4(b). To the extent that using HI taxable earnings captures "true" total wage and salary earnings, the numbers in Table 4(a) are likely to represent reality more closely than those presented in Table 4(b).

■ Conclusion

A thorough understanding of earnings provides valuable insights into the economic well-being of individuals and groups within society. A detailed knowledge of earnings and changes in patterns of earnings is also necessary in order to accurately forecast the financial future of the Social Security program, either under current law or under various plans to reform the program.

This paper uses Social Security Administration data to examine changing earnings distributions in the U.S. over the 1980's and early to mid 1990's. These unique data provide several advantages over data typically used in studies of this sort. Because the earnings information comes directly from the W-2 forms filed by employers, these data minimize the problem of self-reporting errors which are often present in survey data. Also, we are on the verge of having access to even better data for this sort of work as more and more years of HI taxable earnings, with no taxable maximum since 1994, become available. Finally, because of the large number of observations contained within the dataset, I am able to provide better tests of the statistical significance of year-to-year fluctuations in earnings inequality, even when the data are segmented into age and cohort groups.

First and foremost, I find that earnings inequality continues to trend upwards for the overall U.S. population. In an earlier paper which examined the years 1981-1993, I speculated that the upward trend in earnings inequality might have leveled off, or even perhaps reversed, because of a decrease in the S-Gini coefficients over the period 1988-1992. After updating the data and adding two additional years of observations, it seems clear that the dip observed for the years 1988-1992 was merely a pause and that earnings inequality is still trending upwards. The S-Gini coefficients presented in this paper for the years 1992-1995 are statistically significantly higher than those for any other year in the study.

The second important point to be made is that the share of earnings going to the upper decile of the earnings distribution continues to increase at the expense of all other deciles of the distribution. In 1995, nearly 36 percent of all earnings in the U.S. accrued to the 10 percent of the population at the upper end of the earnings distribution. The upper two deciles garnered over 54 percent of the earnings in that year. More work is needed to pinpoint why the earnings share of the upper decile continues to increase, and to consider the long-run effects.

The real mean earnings of those in the 14 to 24 age group fell dramatically (by nearly 25 percent) over the period 1981-1995. Whether this represents a "worsening" of their condition is not clear. The decrease in mean earnings might simply be an indication that more individuals were staying in school longer (and therefore working part-time/part-year jobs) in order to better prepare themselves for future careers. However, it could also be an indication that for many young people, part-year/part-time jobs are the only types of employment available.

Another idea to come from this work is that between-group inequality, when dividing the sample into either various age groups or into various birth cohort groups, is increasing. This is in contrast to a division of groups along race and/or gender dimensions as in Utendorf (1998). Although the increases in between-group inequality presented in this paper are relatively small, they are, nevertheless, real. Still, the contribution to overall earnings inequality by between-group inequality is small when compared to that of within-group inequality.

Future work will examine more thoroughly the changes that have taken place in the upper part of the earnings distribution. In addition, SSA will soon be able to match administrative information on total wage and salary earnings to public-use survey files, such as the Survey of Income and Program Participation and the Current Population Survey. Such matches will provide information on educational attainment and household characteristics, thereby improving the explanatory power of future analyses.

■ Footnotes

1 The CWHS Active file is a 1-percent sample of all individuals with Social Security numbers who have a record of earnings posted to SSA's Master Earnings File.

2 These files also contain other information, such as indications of race and gender, and information for additional years not directly relevant to this study. For a more comprehensive introduction to the CWHS family of files, see Smith (1989).

3 I do not include self-employment income in my analysis. The Social Security Administration receives information on self-employment income only to the extent that it is taxable for OASDI purposes.

4 See Levy and Murnane (1992).

5 Prior to 1978, there is an estimate of total earnings based on taxable earnings up to the taxable maximum. For those individuals at or above the taxable maximum, the estimate of total earnings was derived from the value of the taxable maximum combined with information regarding the quarter in which the individual's taxable earnings reached the taxable maximum.

6 I spent a great deal of time running consistency checks and testing the data in general to determine their fitness for use in this type of exercise. Many of my questions about or problems with the data were cleared up by Creston Smith and his colleagues in SSA's Office of Research, Evaluation, and Statistics' Division of Earnings Statistics and Analysis.

7 Individuals generally have a difficult time legally preventing their actual wage and salary earnings from appearing on their W-2 forms except to the extent that they can contribute to tax-deferred saving plans or to the extent that they participate in the "underground" economy.

[8] In fact, for several years covered by this paper, the top-code limit for wage and salary earnings in the March CPS Supplements was $75,000.

[9] The number of observations varies from year to year depending on the size of the workforce with wage and salary earnings. Also note that it is possible for the observation pool to contain different individuals from year to year because of permanent or temporary changes in employment status.

[10] The early papers in this series on earnings distributions will be limited to descriptive analyses. Future work utilizing a public use dataset linked to SSA administrative data will provide a better basis for explaining the reasons behind the changes seen in patterns of earnings inequality.

[11] Only individuals with positive earnings in one of the earnings variables were included in the sample.

[12] Throughout the paper, I use the phrase "taxable maximum" to refer to the OASDI taxable maximum. The OASDI taxable maximum is automatically updated each year in proportion to the increase in the U.S. average wage level. See any recent *Annual Statistical Supplement* to the *Social Security Bulletin* for more information about the OASDI taxable maximum.

[13] The law limits the amount of wage and salary earnings that one can defer in any given year. In 1995, individuals could defer no more than $9,240 of their pre-tax earnings into 401(k)-type plans, for example.

[14] Obviously, for individuals with true total earnings above the annual maximum taxable earnings amount, this sort of adjustment will capture only part of the missing true total earnings since the Social Security taxable earnings variable does not (generally) exceed the taxable maximum in the dataset. This means that earnings are likely somewhat understated for these high earners and that the earnings inequality measures calculated, therefore, likely understate the true degree of inequality. Social Security taxable earnings are at the taxable maximum while, at the same time, total wage and salary earnings are lower than the taxable maximum in fewer than .7 percent of the observations in any given year. Therefore, the degree to which the earnings measures presented later in the paper are affected should be rather small.

[15] In addition, it is likely that I do not capture any of the deferred compensation for certain other individuals in the sample. For example, there are many observations where reported total wage and salary earnings amounts are greater than the taxable maximum (and therefore greater than the taxable earnings amount). There is not enough information in the dataset to determine whether these individuals had any deferred compensation. Consequently, total wage and salary earnings amounts, particularly for high earners, are probably somewhat understated.

[16] There were fewer than 10 observations for either 1994 or 1995, out of nearly 1.33 and 1.36 million observations, respectively, for which the OASDI taxable earnings variable exceeded the HI taxable earnings variable. For nearly 12 percent of the observations in both 1994 and 1995, the HI taxable earnings variable was greater than the combination of the wage and salary earnings and the deferred compensation variables. In almost 7 percent of the cases, the combination of the wage and salary earnings and the deferred compensation variables exceeded the HI taxable earnings variable. For all other cases, the two were equal.

[17] In 1995, for example, this eliminated about 0.2 percent of the sample.

[18] Thanks go to my colleague, David Weaver, for running a check on some of the more bizarre cases (several individuals well into triple digit ages with large wage and salary earnings amounts reported) against SSA's Master Beneficiary Records. In the vast majority of the cases, it was clear that the earnings files had incorrect years of birth.

[19] See Braun (1988) and Slottje (1989) for a detailed comparison of the various measures of income or earnings inequality.

[20] In other words, $G = \frac{1}{2n^2 \bar{y}} \sum_{i=1}^{n} \sum_{j=1}^{n} | y_i - y_j |$, where y represents earnings. See Deaton and Muellbauer (1986, pp. 232-237) for a thorough discussion of the traditional Gini coefficient.

[21] Like the traditional Gini coefficient, the S-Gini has an intuitive geometric interpretation. Referring back to Figure 1, the S-Gini is twice the weighted area between the Line of Equality and the Lorenz curve, where the weights depend on the observation's rank in the earnings distribution. The S-Gini indices are constructed so that the coefficients must lie between zero and one, just as with the traditional Gini coefficient.

[22] Lorenz curve ordinates can be thought of as "points" along the curve.

[23] Their techniques for deriving the asymptotic variance of the S-Gini estimators do not require knowledge of the underlying distribution from which the data are drawn. This is important in that the 1-percent sample from the CWHS family of files is a stratified cluster probability sample, which would typically affect the sampling errors from estimation. The distribution-free property of the S-Gini indices minimizes the importance of this complication.

[24] See Yitzhaki and Lerman (1991) for a very thorough discussion of stratification and its relationship to measures of inequality, particularly its relationship to the Gini index. Their paper also contains a complete description of the derivation of the stratification indices and their properties.

[25] The decomposition works in the following way. A Gini coefficient, referred to as the within-group Gini, is calculated for each of the individual groups being studied by restricting the sample to members of that group only. Then, an overall within-group inequality term is calculated by multiplying the within-group Gini coefficient for a group by the share of total earnings attributable to that group and summing these products across all groups. Next, a stratification index is calculated for each of the groups in question using the methods set forth by Yitzhaki and Lerman in their paper. An overall stratification term is computed by summing the products of the stratification index for each group, the share of total earnings attributable to that group, the within-group Gini for that group, and one minus the proportion of the sample in the group. Finally, a between-group inequality term is derived for the sample using techniques found in the Yitzhaki and Lerman paper. The overall Gini coefficient is given by the sum of the overall within-group inequality term, the overall stratification term, and the between-group inequality term. Since there is some overlap between the stratification term and the overall within-group inequality and the between-group inequality terms, in the discussion that follows, I will point out where this overlap matters.

[26] Yitzhaki and Lerman (1991), p. 318.

[27] Note that, as indicated in the second section of the paper, there are duplicate tables, labeled (a) and (b). The statistics calculated for years 1994 and 1995 for the (a) tables are generated using the additional earnings information (variables for deferred earnings and HI taxable earnings) available in the files for those two years. The (b) tables do not make use of this additional information, meaning the method used to calculate the total wage and salary earnings variables is consistent across the years of the study.

[28] I used the Total Personal Consumption Expenditures deflator to adjust earnings for changes in the price level over time. All earnings are given in terms of 1992 dollars.

[29] Barrett and Pendakur (1995) use 20 quantiles in their paper. The sensitivity tests they performed indicated that increasing the number of quantiles to 100 did not significantly improve the accuracy of their S-Ginis. Tests I conducted on my sample showed significant improvement in the accuracy

of the estimated S-Gini with an increase of quantiles used from 20 to 100, but little or no gain from increasing the number of quantiles beyond 100. In order to reduce the computational burden, I chose to use 100 quantiles for this paper.

30 As I indicated in the previous section, the S-Gini indices are "ethically tunable" in that one can adjust the parameter to place more weight on the part of the earnings distribution with which one is most concerned. Since the techniques developed by Yitzhaki and Lerman are designed to decompose the traditional Gini coefficient, I chose to use $\delta = 2$, which corresponds to the traditional Gini coefficient, in my S-Gini calculations for consistency across the measures presented in the paper.

31 Whenever I use just the table number, such as Table 1, I am referring to both the (a) and the (b) tables for that number.

32 See Utendorf (1998).

33 While I have enough observations to divide the sample into even more tightly focused age groups, certain of the calculations are fairly computer-intensive. I, therefore, made the decision to focus on the broader groups.

34 Also note that, since 1986, the relative number of 25 to 34 year olds in the sample fell as the baby boom generation moved out of that group and into the 35 to 54 age group.

35 It is not correct to simply divide a coefficient in the "Between-group inequality term" row for a particular year by the coefficient in the "Overall Gini" row for the corresponding year to arrive at a percentage of inequality attributable to between-group inequality. There are components of between-group (as well as within-group) inequality present in the coefficients of the stratification term which would not be properly accounted for by doing this.

36 A different possible configuration of birth cohorts that I might examine in future work would be to use two 10-year birth cohorts prior to the "baby boom" years, a birth cohort spanning the baby boom years (or perhaps one birth cohort spanning the early baby boom and another spanning the late baby boom years), and a final birth cohort covering the "baby bust" years.
